The analysis of a network begins with the elements it contains and the way they are joined. Each branch carries a current, and each node has a potential measured against a common reference. Kirchhoff's laws relate these quantities: t currents entering a node sum to zero, and the voltages around any closed loop sum to zero. With Ohm's law for every resistor, these relations give as many independent equations as there are unknowns, so the circuit can be solved completely. In practice the equations are written so that the number of unknowns stays small, either by choosing loop currents or node voltages as the variables.
